AN ITERATIVE HARD THRESHOLDING ALGORITHM WITH IMPROVED CONVERGENCE FOR LOW-RANK TENSOR RECOVERY

José Henrique de M. Goulart,∗ Gérard Favier

I3S Laboratory, Université de Nice Sophia Antipolis, CNRS, France

ABSTRACT

Recovering low-rank tensors from undercomplete linear measurements is a computationally challenging problem of great practical importance. Most existing approaches circumvent the intractability of the tensor rank by considering instead the multilinear rank. Among them, the recently proposed tensor iterative hard thresholding (TIHT) algorithm is simple and has low cost per iteration, but converges quite slowly. In this work, we propose a new step size selection heuristic for accelerating its convergence, relying on a condition which (ideally) ensures monotonic decrease of its target cost function. This condition is obtained by studying TIHT from the standpoint of the majorization-minimization strategy which underlies the normalized IHT algorithm used for sparse vector recovery. Simulation results are presented for synthetic data tensor recovery and brain MRI data tensor completion, showing that the performance of TIHT is notably improved by our heuristic, with a small to moderate increase of the cost per iteration.

Index Terms—Low-rank Tensor Recovery, Tensor Completion, Iterative Hard Thresholding

1. INTRODUCTION

Tensors having (approximately) low rank arise in many practical applications. Whenever true, this property can in principle be exploited to recover a tensor of interest from undercomplete information given by linear observations, a task which is ill-posed in general. An important special case of this setting is the completion of a data tensor having missing entries under the low-rank assumption. These problems, called low-rank tensor recovery (LRTR) and tensor completion (TC), respectively, are extensions of low-rank matrix recovery (LRMR) and matrix completion [1], and find several applications such as image inpainting [2], seismic signal processing [3], spectral data recovery [4] and machine learning [5].

However, despite being a natural generalization of the matrix rank, the tensor rank is not completely understood and is computationally intractable [6]. Consequently, many existing LRTR techniques rely instead on the multilinear rank, which is a multi-valued quantity composed by the ranks of all mode-

gence speed, which significantly compensates for the increase in computational cost.

2. TENSOR ITERATIVE HARD THRESHOLDING

Let $\mathcal{T} \in U = \mathbb{R}^{N_1 \times \cdots \times N_r}$ be a $P$th-order tensor and denote by $\mathcal{T}_r$ the mode-$p$ unfolding (matricization) of $\mathcal{T}$ [7]. The multilinear rank (m-rank) of $\mathcal{T}$ is a $P$-tuple given by $\text{m-rank}(\mathcal{T}) = (\text{rank}(\mathcal{T}_1), \ldots, \text{rank}(\mathcal{T}_P))$ [8].

In view of the computational difficulty of minimizing the tensor rank, the LR TR problem is tackled in [13] by imposing a component-wise bound $r = (R_1, \ldots, R_P)$ on the m-rank of the solution, which is sought in the least-squares sense in $L_r = \{ \mathcal{T} \in U : \text{rank}(\mathcal{T}_p) \leq R_p, p = 1, \ldots, P \}$. This leads to the constrained formulation

$$
\min_{\mathcal{T} \in L_r} J(\mathcal{T}), \quad \text{with} \quad J(\mathcal{T}) = \| y - \mathcal{A}(\mathcal{T}) \|_F^2, \quad (1)
$$

where $\mathcal{A} : U \mapsto \mathbb{R}^M$ is a linear measurement operator and $y \in \mathbb{R}^M$ is a given vector of measurements. We denote by $\mathbf{A}$ the matrix representation of $\mathcal{A}$ such that $\mathcal{A}(\mathcal{T}) = \mathbf{A} \mathbf{c}(\mathcal{T})$, where $\mathbf{c}()$ stacks the elements of its argument in a long vector. Note that (1) applies in particular to the TC problem, where $\mathcal{A}$ is constrained to be a sampling operator; in other words, $\mathbf{A}$ has $M$ canonical vectors of $\mathbb{R}^{N_1 \times \cdots \times N_r}$ as rows.

To solve (1), [13] proposes the TIHT algorithm

$$
\mathcal{T}_k = \mathcal{H}_r(\mathcal{T}_{k-1} + \mu_k \mathcal{A}^* (y - \mathcal{A}(\mathcal{T}_{k-1}))), \quad (2)
$$

where $\mathcal{A}^* : \mathbb{R}^M \mapsto U$ is the adjoint of $\mathcal{A}$ (i.e., $\mathcal{A}^* = \text{unvec}(\mathbf{A}^T \mathbf{x})$, where $\text{unvec}()$ is the inverse of $\text{vec}()$), $\mu_k > 0$ is a step size parameter and $\mathcal{H}_r : U \mapsto L_r$ maps a tensor $\mathcal{T}$ into the $r$-truncation of its higher-order SVD (HOSVD). More concretely, writing this HOSVD as $\mathcal{T} = \mathcal{S} \times_1 U_1^{(1)} \times_2 \cdots \times_P U_1^{(P)}$, where $\mathcal{S} \in U$ is the core tensor and $U_1^{(p)} \in \mathbb{R}^{N_p \times N_r}$ is the matrix of $p$th-mode singular vectors, $\mathcal{H}_r(\mathcal{T}) = \mathcal{S} \times_1 U_1^{(1)} \cdots \times_P U_1^{(P)}$, where $U_1^{(p)}$ contains the first $R_p$ columns of $U_1^{(p)}$ and $\mathcal{S} \in \mathbb{R}^{R_1 \times \cdots \times R_P}$ satisfies $[\mathcal{S}]_{r_1,\ldots,r_P} = [\mathcal{S}]_{r_1,\ldots,r_P}$ for all $r_p \in \{1, \ldots, R_p\}$. The formula given in [13] for $\mu_k$ can be written as

$$
\mu_k = \| \mathcal{G}_{k-1} \|_F^2 \| \mathcal{A}^* (\mathcal{G}_{k-1}) \|_F^2, \quad (3)
$$

where $\mathcal{G}_{k-1} \triangleq -\mathcal{A}^* (y - \mathcal{A}(\mathcal{T}_{k-1})))$. It is easy to show that, in the TC setting, $\mu_k = 1$ and the TIHT algorithm is equivalent to the HOSVD-based scheme proposed in [3] (with $a = 1$), because of the special form of $\mathcal{A}$.

As $2\mathcal{G}_{k-1}$ is the gradient of $J$ at $\mathcal{T}_{k-1}$, one can see that TIHT first updates the current estimate $\mathcal{T}_{k-1}$ with a gradient descent step and then computes an approximation of the result in the feasible set. This is therefore very similar in spirit to the projected gradient algorithm [15], in which such approximation is the projection onto the feasible set. Yet, as projecting onto $L_r$ amounts to solving a best rank-$(R_1, \ldots, R_P)$ approximation problem, which is NP-Hard [6] and requires using costly algorithms (see, e.g., [16]), a low-rank approximation given by the truncated HOSVD is used instead. This is a widely used technique which, despite being suboptimal, gives an approximant satisfying $\| \mathcal{H}_r(\mathcal{T}) - \mathcal{T} \|_F \leq \sqrt{r} \| \mathcal{T} - \mathcal{T} \|_F$, where $\mathcal{T}$ is a minimizer of the Euclidean distance to $\mathcal{T}$ in $L_r$ [8]. Apart from the suboptimality of $\mathcal{H}_r$, it is important to point out that the optimality condition underlying the projected gradient algorithm applies only to convex feasible sets [15], which is not the case for $L_r$. One might then wonder how TIHT actually achieves recovery.

In the following, relying on the optimization strategy developed by [14], we further study the TIHT algorithm. This study will then serve as a basis for devising a new step size selection routine in order to improve its convergence speed.

3. MONOTONICALLY DECREASING OBJECTIVE VALUES VIA MAJORIZATION-MINIMIZATION

The NIHT algorithm proposed in [14] is based on a clever MM strategy devised to minimize $\| y - \Phi x \|_2^2$ subject to $x \in V_s \subset \mathbb{R}^N$, where $V_s$ is the subset of $s$-sparse vectors of $\mathbb{R}^N$ and $y \in \mathbb{R}^M$ is the linear measurement of an $s$-sparse vector of interest given by $\Phi = \mathbb{R}^{M \times N}$. As shown in [14], the NIHT iterates have monotonically decreasing cost function (or objective) values and are convergent. Yet, whether this strategy promptly carries over to other similar problems, as (1), is not immediately clear. In what follows, we show that this is true for problem (1) and that the TIHT algorithm can be interpreted as an extension of this MM approach.

Recall that, to minimize a cost function $J$, an MM algorithm proceeds by minimizing instead at each iteration $k$ a surrogate function $J_k$ which majorizes $J$ and coincides with it at the current estimate. It is not difficult to see that iterates computed in that manner are driven downhill with respect to $J$. The interest lies in the possibility of constructing surrogate functions $J_k$ which are easier to minimize than $J$ under the considered constraints.

In the case of TIHT, given the current estimate $\mathcal{T}_{k-1}$ and a constant $\mu_k$ such that

$$
J_k(\mathcal{T}) \triangleq \mu_k J(\mathcal{T}) + \| \mathcal{T} - \mathcal{T}_{k-1} \|_F^2 - \mu_k \| \mathcal{A}^* (\mathcal{T} - \mathcal{T}_{k-1}) \|_F^2, \quad (4)
$$

satisfies $\mu_k J(\mathcal{T}_k) < J_k(\mathcal{T}_k)$ for all $\mathcal{T} \neq \mathcal{T}_{k-1}$, we minimize $J_k$ over $L_r$ to obtain a new estimate $\mathcal{T}_k$. Note that such a $\mu_k$ always exists, since we can choose it such that $0 < \mu_k < \| \mathcal{A}^* \|^{-2}$. Hence, if the minimizer $\mathcal{T}_k$ of $J_k$ over $L_r$ satisfies $\mathcal{T}_k \neq \mathcal{T}_{k-1}$, then we have $\mu_k J(\mathcal{T}_k) < J_k(\mathcal{T}_{k-1}) \leq J_k(\mathcal{T}_{k-1}) = \mu_k J(\mathcal{T}_{k-1})$, thus yielding $J(\mathcal{T}_k) < J(\mathcal{T}_{k-1})$.

Let us now consider the minimization of $J_k$ over $L_r$. Replacing $J(\mathcal{T})$ by (1) in (4), we have $J_k(\mathcal{T}) = \| \mathcal{T} - \mathcal{T}_{k-1} \|_F^2 + \mu_k \| y - \mathcal{A}(\mathcal{T}_{k-1}) \|_2^2 - 2 \mu_k \langle y, \mathcal{A}(\mathcal{T}_{k-1}) \rangle - \mu_k \| \mathcal{A}^* (\mathcal{T}_{k-1}) \|_2^2$, which is clearly strictly convex. Therefore, solving $J_k^*(\mathcal{T}) = 0$ yields the unique unconstrained minimizer

$$
\mathcal{T}^* = \mathcal{T}_{k-1} + \mu_k \mathcal{A}^* (y - \mathcal{A}(\mathcal{T}_{k-1})). \quad (5)
$$

Now, for any $S \subset U$ and all $\mathcal{T} \in U$, let us define $\Pi_S : U \mapsto 2^S$, where $2^S$ denotes the power set of $S$, as $\Pi_S(\mathcal{T}) = \bigcap_{\mathcal{U} \in \Pi_S} \mathcal{U}$.
arg min_{X \in S} \|X - T\|_F. Clearly, if S is a closed nonempty convex set, \(\Pi_S(T)\) contains exactly one element: the projection of \(T\) onto \(S\). If \(S\) is not convex but is closed and nonempty, then \(\Pi_S(T)\) is still nonempty (by the extreme value theorem, coercivity and continuity of \(\|X - T\|_F\)), but might contain multiple elements. Relying on the definition of \(\Pi_S\), the next result shows how a minimizer of \(J_k\) over \(L_\tau\) can be obtained from \(T^*\).

**Proposition 3.1.** Let \(S \subset U\) be a closed nonempty set. Then, \(\Pi_S(T^*)\) is the set of minimizers of \(J_k(T)\) over \(S\), where \(T^*\) is given by (5).

**Proof.** Since \(S\) is closed and nonempty, \(J_k\) is continuous and \(J_k(T) \to \infty\) for \(\|T\|_F \to \infty\), \(J_k\) admits at least one minimum in \(S\). Also, for any \(T \in S\), we can write \(T = T^* + Z\) for some \(Z \in U\) and then rewrite \(J_k\) as

\[
J_k(T^* + Z) = J_k(T^*) + \|Z\|_F^2 + 2\langle Z, T^* - T_k-1 \rangle - 2\mu_k(\langle Z, y - \langle T, k-1 \rangle \rangle)
\]

\[
= J_k(T^*) + \|Z\|_F^2 + 2\langle Z, T^* - T_k-1 \rangle + 2\mu_k(Z, G_{k-1})
\]

\[
= J_k(T^*) + \|Z\|_F^2,
\]

where the last equality follows directly from (5). Hence, as \(Z = T = T^*\), we have the equivalence

\[
\arg\min_{T \in S} J_k(T) = \arg\min_{T \in S} \|T - T^*\|_F^2 = \Pi_S(T^*).
\]

Since \(L_\tau\) is closed and nonempty, we have from Proposition 3.1 that, if there is some \(\mu_k\) such that \(J_k(T)\) majorizes \(\mu_k J(T)\) and for which there exists \(T_k \in \Pi_{L_\tau}(T_{k-1} + \mu_k G_{k-1})\) satisfying \(T_k \neq T_{k-1}\), then \(J(T_k) < J(T_{k-1}).\) It turns out, however, that the requirement of having a \(J_k(T)\) that majorizes \(\mu_k J(T)\) for all \(T\) can be relaxed to improve convergence speed, as discussed in the next section.

It should be noted that it is hard to ensure in practice that \(T_k\) is indeed a minimum of \(J_k\) over \(L_\tau\), because projecting onto \(L_\tau\) is not an easy task. To avoid an excessive computational cost per iteration, TIHT employs the quasi-optimal projection \(\mathcal{H}_\tau\), and thus \(T_k\) is only close to a minimum. Nevertheless, as observed by [13], practical experience suggests that this suboptimality does not preclude TIHT from converging. Yet, a more rigorous analysis taking it into account remains as a topic for future investigation.

**Remark 3.2.** Interestingly, Proposition 3.1 is quite general, being valid for any closed nonempty subset \(S\). Thus, the above reasoning clearly holds for other formulations as, e.g., one based on the rank definition which applies to the tensor train model (see [8] and references therein). More generally, it can be extended to any problem of the form (1) in a finite-dimensional Hilbert space, as long as the feasible set is closed and nonempty.

### 4. IMPROVED STEP SELECTION STRATEGY

In spite of the successful recovery results shown in [13], the suitability of the step size formula (3) for achieving actual decrease of \(J\) is not discussed. This formula provides the optimal gradient descent step for unconstrained minimization (i.e., over \(U\)). However, when minimizing over \(L_\tau\) with the scheme (2), its optimality is lost. Equally importantly from a practical standpoint, the behavior of the resulting algorithm is not satisfactory, because it converges quite slowly.

In the previous section, we have used the inequality \(\mu_k J(T_k) < J_k(T_k)\) to derive \(J(T_k) < J(T_{k-1}).\) Thus, it suffices to guarantee that this inequality holds at \(T_k\), instead of requiring that \(J_k(T)\) majorizes \(\mu_k J(T)\) at all \(T\). To this end, one can check whether \(\mu_k\) satisfies

\[
\mu_k < \omega(\mu_k) = \frac{\|T_k - T_{k-1}\|_F^2}{\|\delta(T_k - T_{k-1})\|_F^2}
\]

because such inequality, together with (4), implies \(\mu_k J(T_k) < J_k(T_k)\). Note that the notation \(\omega(\mu_k)\) emphasizes that the bound for \(\mu_k\) depends on \(\mu_k\) itself.

The condition (6) is an extension of that proposed in [14] for NIHT, which ensures cost function decrease when an optimal step cannot be computed with a simple formula. In that situation, NIHT only accepts a candidate step size if it satisfies a condition analogous to (6); otherwise, it is reduced until that condition is fulfilled. In the case of TIHT, (6) was not violated by step sizes computed with (3) during our practical experiments. However, (3) often yields \(\mu_k \ll \omega(\mu_k)\), while empirical evidence suggests that the optimal step lies usually closer to its bound. This slows down the convergence of the algorithm. Note that, since any \(\mu_k\) satisfying \(\mu_k < \|\delta\|_F^2\) is majorized by (3), this observation also justifies the use of the more relaxed condition (6).

To circumvent this problem, we propose a modified algorithm, named improved-step-selection TIHT (ISS-TIHT), in which a heuristic step selection routine is added. The idea behind this routine is simple: given a fixed \(\alpha\) such that \(0 < \alpha < 1\), one checks whether the candidate \(\mu_k\) satisfies

\[
\omega(\mu_k) \leq \mu_k < \omega(\mu_k),
\]

keeping its associated estimate \(T_k\) when it does. Otherwise, we simply set \(\mu_k = \beta \omega(\mu_k)\) for some \(\beta \in (\alpha, 1)\), compute a new \(T_k\) and repeat the process. We employ (3) as the starting candidate \(\mu_k\), which is reasonable since it satisfies (7) at some iterations. As there is no guarantee of finding a step fulfilling (7) with this procedure, we establish a maximum number of trials \(L\), after which we keep the biggest generated step size satisfying the upper bound of (7). If none of them does, we take the smallest candidate step and proceed as in the NIHT [14], reducing it via division by a factor \(\kappa > 1\) until the upper bound is verified. A pseudocode describing this scheme is shown in Algorithm 1, where we denote the candidate values of \(\mu_k\) and \(T_k\) by \(\mu_{k,l}\) and \(T_{k,l}\), respectively, for \(l = 1, \ldots, L\).
Algorithm 1 ISS-TIHT

1: for $k = 1, 2, \ldots, K$ do
2: $\mathcal{G}_{k-1} = -\nabla \mathcal{L}(\mathcal{Y} - \nabla \mathcal{L}(\mathcal{T}_{k-1}))$
3: $\mu_{k,1} = \|\mathcal{G}_{k-1}\|_F^2 / \|\nabla \mathcal{L}(\mathcal{G}_{k-1})\|_F^2$
4: for $l = 1, \ldots, L$ do
5: $\mathcal{T}_{k,l} = \mathcal{T}_{k-1} - \mu_{k,l} \mathcal{G}_{k-1}$
6: if $\alpha \omega(\mu_{k,l}) \leq \mu_{k,l} \leq \omega(\mu_{k,l})$ then
7: select $\mu_k = \mu_{k,l}, \mathcal{T}_k = \mathcal{T}_{k,l}$
8: break
9: end if
10: end for
11: if no $\mu_{k,l}$ was selected then
12: if $\exists l$ such that $\mu_{k,l} < \omega(\mu_{k,l})$ then
13: $l^* = \arg \max_l \mu_{k,l}$ subject to $\mu_{k,l} < \omega(\mu_{k,l})$
14: else
15: $l^* = \arg \min_l \mu_{k,l}$
16: while $\mu_{k,l} \geq \omega(\mu_{k,l})$ do
17: $\mu_{k,l} = \Omega(\mu_{k,l})$
18: end while
19: end if
20: end if
21: select $\mu_k = \mu_{k,l^*}, \mathcal{T}_k = \mathcal{T}_{k,l^*}$
22: end if
23: end for

We point out that the idea of choosing a new candidate for the step size as $\beta \omega(\mu_k)$ is suggested in [14] with $\beta = 1$, but only in the case that the current candidate violates the upper bound $\omega(\mu_k)$. In other words, a candidate step size is never increased in NIHT; rather, it is only shrunk if the upper bound $\omega(\mu_k)$ is not met. In the case of TIHT, enforcing also the lower bound of (7) substantially accelerates convergence.

5. SIMULATION RESULTS

We now evaluate ISS-TIHT in two simulation scenarios. First, a LRTR setting with an unconstrained operator and a synthetic data tensor is considered. To this end, we randomly generate $\mathcal{A}$ and $\mathcal{T} \in \mathbb{R}^{N \times N \times N}$ and apply four algorithms to recover $\mathcal{T}$ from $\mathcal{Y} = \mathcal{A}(\mathcal{T}) = \text{vec}(\mathcal{T})$, where $\mathcal{A} \in \mathbb{R}^{M \times N^3}$, with $M = \rho N^3$. The data tensor is given by $\mathcal{T} = \mathcal{T}_{0} + 10^{-3} \mathcal{N}$, where $\mathcal{T}_0$ is a low-rank tensor generated via $\mathcal{T}_0 = \mathcal{S} \times_1 \mathcal{V}^{(1)} \times_2 \mathcal{V}^{(2)} \times_3 \mathcal{V}^{(3)}$, with $\mathcal{S} \in \mathbb{R}^{R \times R \times R}$ and $\mathcal{V}^{(p)} \in \mathbb{R}^{N_p \times R}$. All $\mathcal{A}, \mathcal{N}, \mathcal{S}$ and $\mathcal{V}^{(p)}$ have standard Gaussian i.i.d. elements, and we normalize $\mathcal{T}_0$ and $\mathcal{N}$ so that $\|\mathcal{T}_0\|_F = \|\mathcal{N}\|_F = 1$. The evaluated algorithms are TIHT, ISS-TIHT, and ADMM, an alternating direction method of multipliers (ADMM) scheme based on that of [10, Sec. 4.4], which minimizes a weighted sum of NNS of matrix unfoldings, and a generalized alternating least-squares (GALS) scheme, which estimates the components of a low-rank Tucker model of $\mathcal{T}$ by minimizing $J$ with respect to them in an alternating fashion. We empirically set the regularization and penalty parameters of ADMM respectively as $\lambda = 10^{-2}$ and $\eta = 2$, aiming at maximizing estimation precision, and use weights $\gamma_1 = \gamma_2 = \gamma_3 = \frac{1}{3}$. Regarding ISS-TIHT, we use $\alpha = 0.5$, $\beta = 0.7$, $\kappa = 1.2$ and $L = 5$. We fix $R = 5, N = 20, \rho = 0.15$ and let all the algorithms run for $K = 60$ iterations, measuring at each iteration $l$ the normalized square error $\text{NSEE}_k = \|\mathcal{T} - \mathcal{T}_k\|_F^2 / \|\mathcal{T}\|_F^2$. TIHT, ISS-TIHT and GALS are run with $R_1 = R_2 = R_3 = R$. This procedure is repeated for 30 joint realizations of $\mathcal{A}, \mathcal{T}_0$ and $\mathcal{N}$, and the average NSEE is computed for each $k$ and each algorithm, yielding the corresponding normalized mean-square error NSEEk displayed in Fig. 1.

Table 1 reports the average computing time per iteration measured in a Intel Xeon ES-2630v2 2.60 GHz. The results show that ISS-TIHT converges much faster than TIHT. GALS converges even faster, but at the expense of a much higher computational cost. Since ADMM performs poorly with $M$ measurements, we also evaluate it using the same procedure but with $\mathcal{A}$ providing 2M and 3M measurements. As the curves show, only with 3M measurements ADMM attains low error (at a quite high cost), but is still outperformed by ISS-TIHT and GALS.

In the second scenario, we consider a TC setting. The data tensor $\mathcal{T} \in \mathbb{R}^{128 \times 128 \times 128}$ now contains the brain MRI data used in [17]. The evaluated algorithms are the ADMM scheme of [10, Sec. 4.4], TIHT and ISS-TIHT. GALS and the approach of [17] are not included since the first is too costly for this setting, while the latter does not apply to TC. The ADMM algorithm is employed with the observations as constraints ($\lambda \to 0$), as proposed in [10] for the noiseless

Table 1. Average time measured per iteration (in seconds).
One can see that, thanks to the introduction of ISS-TIHT, we set (again, empirically) \( \eta = 0.04 \), and choose \( \gamma_1 = \gamma_2 = \gamma_3 = 1/3 \). For ISS-TIHT, we use \( \alpha = 0.5, \beta = 0.7, \kappa = 1.2 \) and \( L = 5 \). TIHT and ISS-TIHT are run with \( R_1 = R_2 = R_3 = R = 20 \). To generate data, we randomly choose a subset of the indices of \( \mathcal{T} \) of cardinality \( M = \rho 128^3 \), with \( \rho = 0.15 \), filling \( y \) with the corresponding elements. This process was repeated for 30 realizations of \( A \). The results are shown in Table 1 and Fig. 2. Again, we plot the NSE of the \( (R, R, R) \)-truncated HOSVD of \( \mathcal{T} \), which is an approximate lower bound for the NMSE of both TIHT and ISS-TIHT. One can see that, thanks to the introduced step selection heuristic, ISS-TIHT outperforms both TIHT and ADMM.

Finally, we point out that, in all our experiments, ISS-TIHT always found at least a candidate step size satisfying the upper bound of (7). Also, the behavior of the algorithm was not observed to be too sensitive to the choice of \( \alpha \) and \( \beta \).

6. CONCLUSION

We have studied the TIHT algorithm by relying on the optimization strategy which underlies the NIHT algorithm. This offers an insightful interpretation of its iterates, whose cost function values are monotonically decreasing under a certain upper bound on the step size, assuming the best low-rank approximation calculated at each iteration is exact. Then, we have proposed the ISS-TIHT algorithm, which includes a subroutine that attempts to find a step within a constant factor of its bound. Our simulation results show that this simple heuristic leads to a remarkable acceleration of convergence.
